Summary Pigment gallstones, which are much less frequent than cholesterol stones, are classified descriptively as “black” or “brown”. They are composed mostly of calcium hydrogen bilirubinate, Ca(HUCB)\textsubscript{2}, which is polymerized and oxidized in “black” stones but remains unpolymerized in “brown” stones. Black stones form in sterile gallbladder bile but brown stones form secondary to stasis and anaerobic bacterial infection in any part of the biliary tree, including the gallbladder. Other calcium salts coprecipitate in both stone types; crystalline calcium phosphate and/or carbonate in the case of “black” stones and amorphous calcium salts of long chain saturated fatty acids (“soaps”) in the case of “brown” stones. Cholesterol is present in variable proportions in “brown” more than “black” stones and in the latter, the bile sterol may be totally absent. The “scaffolding” of both stone types is a mixed mucin glycoprotein matrix secreted by epithelial cells lining the biliary tree. The critical pathophysiological prerequisite for “black” stone formation is “hyperbilirubinbilia” (biliary hypersecretion of bilirubin conjugates). It is due principally to hemolysis, ineffective erythropoiesis, or pathologic enterohepatic cycling of unconjugated bilirubin. Endogenous biliary β-glucuronidase hydrolysis of bilirubin conjugates in gallbladder bile provides HUCB\textsuperscript{−} molecules that precipitate as insoluble salts with ionized Ca. Putatively, reactive oxygen species secreted by an inflamed gallbladder mucosa are responsible for transforming the initial soft yellow precipitates into hard black [Ca(HUCB)\textsubscript{2}]\textsubscript{n} polymers. Despite “brown” gallstones being soft and amenable to mechanical removal, chronic anaerobic infection of the biliary tree is often markedly resistant to eradication.

Introduction

Although cholesterol gallstones can contain as much as 30% calcium bilirubinate and are sometimes called “mixed” stones [1], pigment gallstones are distinct containing calcium bilirubinate, Ca(HUCB)\textsubscript{2}, as the principal component.

They are classified descriptively as "black" stones, which are hard, and "brown" stones, which are soft [2]. True prevalence as opposed to clinical, autopsy or surgical prevalence in free-living populations has not been determined. Black stones are mostly amorphous, containing primarily polymerized calcium monooacidic unconjugated bilirubin, Ca(HUCB)₂. They often contain crystalline salts of calcium phosphate and/or calcium carbonate in one of its polymorphic forms, calcite, aragonite or vaterite and may also contain many metals found in bile [3]. They form in sterile gallbladder bile, and the principal risk factor is "hyperbilirubinemia" [4] (secretion of excess bilirubin conjugates into bile). This results particularly from hemolysis from any cause, ineffective erythropoiesis or induced enterohemepatic cycling (EHC) of unconjugated bilirubin (UCB), which we focus on in this review. Other causes of "black" stones are gallbladder hypomotility, secondary to diabetes mellitus [2], total parenteral nutrition [2] and truncal vagotomy [4]. Neither intensive blue-light phototherapy for hyperbiliru-
binemia in neonates and Crigler-Najjar syndrome Type 1 patients [5], nor excessive sun exposure has been proven to cause black pigment gallstone formation [6]. Blue light leads to biliary and urinary excretion of water-soluble configuralional as well as structural UCB photoisomers. These rapidly revert to the more stable but insoluble natural Z-Z photoisomer in bile [7,8]. It is not surprising therefore that cholestasis can result from phototherapy due to massive pre-
cipitation of bile pigment in the small intrahepatic bile ducts [9,10]. The "baby syndrome" is due to retention of the geometric isomer, photobilirubin II in the skin of infants with phototherapy-induced cholestasis [11].

"Brown" gallstones are invariably laminated, contain unpolymerized Ca(HUCB)₂ co-precipitated with amorphous calcium salts of palmitate and stearate (calcium "soaps") derived from bacterial phospholipase A₁ hydrolysis of biliary phosphatidylcholines [12]. They also contain unconjugated (free) bile acids [2] and Ca bile salts and variable amounts of cholesterol. This contrasts with "black" stones, in which the bile sterol is often absent [2].

"Brown" stones may occur anywhere in the biliary tree but rarely in the gallbladder. They are associated with anaerobic bacterial infection secondary to obstruction and/or stasis of any etiology [13], including parasitic infestation from nematodes and flukes [14]. Thick section electron microscopy reveals bacterial cytoskeletons within the stones' structures [15]. A migratory chol-
esterol/black pigment gallstone that escapes the gallbladder and becomes impacted in the bile duct is frequently the cause of stasis and secondary bacterial infection [16]. An often overlooked cause of biliary stasis-associated brown stones is a juxtapapillary duodenal diverticulum harboring anaerobes [17]. In developing and tropical countries, the bile-seeking worms that are initiating factors are Ascaris lumbricoides, Clonorchis sinensis [18] and Opisthorchis viverrini [19]. In contrast to black pigment stones that are usually radiopaque, brown pigment gallstones are radiolu-

cent.

For brown gallstones to form, the biliary tree must become infected with colonic anaerobic microbiota pro-
ducing β-glucuronidase, an enzyme that hydrolyzes bis-
glucuronosyl bilirubin to UCB. Bacterial production of detergent-resistant phospholipase A₁ produces free palmitic and stearic acids, the products of hydrolysis of the sn-1 ester linkage of biliary phosphatidylcholines [12]. These precipitate with calcium counter-ions as long-chain insoluble soaps [2]. The amide linkage of conjugated bile salts is hydrol-
yzed by cholyglycylamide, which is secreted by many anaerobic strains of bacteria (e.g. Streptococcus faecalis, Clostridium spp., Bacteroides spp.) [20], forming free i.e. unconjugated bile acids. These are capable of precipitating as insoluble bile acids per se or less likely as calcium bile salts [21]. Provided marked stasis is present, "brown" pigment gallstones may develop exceptionally under apparently "sterile" conditions, such as throughout the biliary tree in patients with Caroli’s syndrome or in isolated choledochal cysts [22].

Because hyperbilirubinemia is the critical risk factor, black stones are associated frequently with all major hemolytic anemias e.g. spherocytosis [23], sickle cell disease [24], thalassemia [25], and also with subclinical hemolysis from prosthetic valve replacements [26], malaria [27], hypersplenism from hepatic cirrhosis [28], and foot trauma in long-distance runners [29]. Ineffective erythropoiesis typically secondary to folate and vitamin B₁₂ deficiencies [30] is now rare but can complicate thalassemia as well as sickle cell disease. Other conditions associated with increased prevalence of black pigment gallstones are Gilbert’s syndrome [31], associated with enhanced biliary secretion of monoglucuronosyl bilirubin, and hyperparathyroidism [32], associated with higher levels of ionized calcium in bile.

Acquired EHC of UCB as a cause of hyperbilirubinemia and black pigment stone formation is a newly described pathophysiological and clinical entity [33]. Its principal causes are ileal dysfunction, disease, resection or bypass, and various dietary influences on ileal function, such as high carbohydrate or cholesterol intake, or alcohol abuse [33]. Although absence of biliary infection has always been the basic pre-
requirement for black pigment gallstone formation, recent data suggest that they might also be primed by biles infected with "nanobacteria" that produce hydroxyapatite [34] as was also suggested for nephrolithiasis [35]. These claims have not been further elucidated clinically or experimentally. Fig. 1 summarizes the proven concepts underlying the pathobiology of black (A) and brown (B) pigment stone formation in humans.

### Physical-chemistry of "black" and "brown" pigment gallstone formation

UCB, the end product of heme catabolism, is an open-chain tetrapyrrole molecule whose outer monopyrroles are inter-
connected by rigid —CH₂— linkages and the dipyrrrole units by a flexible central —CH₂— bridge. The central pyrrole rings subend two carboxyethyl side-chains, which in aqueous

1 Although this neologism is a dyshonic tongue-twister, we believe that it is useful for communication and reflects the etymology of the time-honored "hyperbilirubinemia". "Hyperbilirubinbinilia" is not our coinage but that of a distinguished bilirubinologist and editorialist, RD Soloway [Gastroenterology 1996;110:2013–14].
Pathogenesis of pigment gallstones

In A. Increased HUCB\(^{−}\) levels in bile arise from endogenous acidic β-glucuronidase, principally of hepatic origin that hydrolyzes excess bilirubin glucuronides in bile (hyperbilirubinemia) to UCB. Deficiency of solubilizers for Ca\(^{2+}\), monoacidic unconjugated bilirubin (HUCB\(^{−}\)), and Ca bilirubinates (bile salt-cholesterol micelles, bile salt-lecithin-cholesterol micelles, and unilamellar lecithin-cholesterol vesicles) leads to increases in free Ca\(^{2+}\) ions and free bilirubinate anions. Likewise, increases in free Ca\(^{2+}\) ions may be due to increased secretion into the biliary tree. In slightly alkaline bile, the concentrations of other Ca\(^{2+}\)-sensitive anions, such as carbonate and phosphate, may also increase. When the ion products of the Ca-anion salts exceed their equilibrium solubility products in bile, the biliary system becomes supersaturated and precipitation is thermodynamically possible. Mucin glycoproteins are hypersecreted by the gallbladder mucosa like in other lithogenic settings and form a biliary gel providing a nucleation matrix for the precipitated pigment salts. Cholesterol may or may not phase-separate depending on its level in bile and is absent in stones when the cholesterol saturation index (CSI) of bile is less than 1 as occurs in most black pigment stone gallbladder bile.

Solid-state "attack" by free radicals or singlet oxygen (reactive oxygen species, ROS), from an inflamed gallbladder mucosa leads to tetrypyrrole polymerization and oxidation, which imparts the black spicular appearance to most of these stones. In B. stasis, due to motor disorders of the sphincter of Oddi, strictures from biliary surgery or foreign bodies, such as gallstones from the gallbladder, strictures, parasites and their eggs and carcasses (principally from nematodes and flukes), facilitate anaerobic bacterial invasion and overgrowth. Lithogenesis, stasis and infection lead to hypersecretion of biliary tree mucin glycoproteins that form a gel in bile. Bacterial enzymes catalyze the hydrolysis of ester and amidic linkage in all biliary lipids: Phospholipase A\(_{2}\) catalyzes hydrolysis of biliary phosphatidylycerolines at the sn-1 position to produce palmitic and stearic acids plus lysophosphatidylycholine, β-glucuronidase catalyzes hydrolysis of bilirubin glucuronosides to produce UCB and glucuronic acid which acidifies bile further, conjugated bile salt hydrolyase (cholylglycylamidase) catalyzes hydrolysis of the amidic linkage of conjugated bile salts to produce free (unconjugated) bile acids, taurine, or glycine. Saturated fatty acids can precipitate per se but typically form insoluble calcium soaps with Ca\(^{2+}\) ions; UCB forms insoluble acidic calcium bilirubinate salts Ca(HUCB)\(_{2}\), and free secondary bile acids may precipitate as such, or less commonly as calcium salts. Lysophosphatidylycholine may act as a fusogen for cholesterol-containing unilamellar phospholipid vesicles, leading to nucleation of cholesterol monohydrate crystals that are invariably co-precipitated with brown stones. The calcium salts, cholesterol, and biliary tree mucins, the major components of "brown" pigment stones, also act as a "trap" for the anaerobic bacteria making their elimination difficult; bacterial "skelton" are usually visualized by electron microscopy of thick-sections of these stones. Ductal obstruction by brown stones themselves perpetuates the vicious cycle of stasis and chronic anaerobic bacterial infection.

systems ionize only at alkaline pH values [36]. Because of six intramolecular hydrogen bonds [36], UCB, which is in the H\(_{2}\)UCB form at physiological pH values, is highly insoluble in aqueous media (< 70 nM) [37]. However, at pH values of human hepatic (7.3–8.7) and gallbladder (6.2–7.8) bile [2], UCB is a monoacidic species (HUCB\(^{−}\)) principally because of the presence of high concentrations of bile salts. Nevertheless, it is exquisitely sensitive to precipitation as the

monoacid salt with typical biliary concentrations of ionized Ca [2,38]. In contrast, mono- and bisglucuronosyl bilirubins, the predominant conjugated bile pigment species in human and most laboratory animal bile, bind ionized calcium as soluble salts and are not precipitated with physiological calcium concentrations [39]. Increased plasma ionized calcium concentrations, a hallmark of hyperparathyroidism, also seems to be a risk factor for black pigment gallstone disease [32] due to the rapid equilibration of ionized calcium, which has a small hydrated radius, between intravascular and biliary compartments.

Several physiological and biochemical mechanisms solubilize UCB in aqueous environments:

- binding to albumin or HDL in plasma;
- binding to bile salt monomers, dimers and micelles [40], mucin glycoproteins in bile and intestinal lumen [41];
- covalent linkage of one or both—COOH groups with glucuronic acid catalyzed by hepatic bilirubin UDP-glucuronosyl transferase (UGT1A1) producing monoglucuronosyl bilirubins and bisglucuronosyl bilirubins;
- disruption of internal hydrogen bonding by phototherap-
  induced isomerization of UCB forming water-soluble structural and configurational isomers [42] or;
- binding to unilamellar vesicles in cholesterol supersatu-
  rated bile [2].

Increased proportions of biliary monoglucuronosyl biliru-
bin to bisglucuronosyl bilirubin are the rule in bile of patients with black pigment gallstones [43,44]. Monoglucuronosyl bilirubin can more easily be deconjugated in bile by endogenous acidic β-glucuronidase that is secreted by hepatic parenchymal cells [45], or less frequently by biliary epithelial β-glucuronidase and non-enzymatic hydrolysis [46]. An increase in the absolute concentration of biliary UCB has been reported in humans and animals with black pigment gallstones, as well as early calcium bilirubinate precipitates [47,48]. Calcium bilirubinate precipitates may also serve as seed nuclei during the initiation of choles-
sterol cholelithiasis [48,49]. In addition, human “biliary sludge” consists of calcium, monoconjugated and uncon-
jugated bilirubins plus mucin glycoproteins, and may serve as a matrix in which pigment or cholesterol stones develop [49]. Because human pigment gallstones invariably contain a mucin glycoprotein matrix, or “scaffolding” [50], it is likely that hypersecretion of mucin by the gallbladder, as observed in animal models of pigment gallstones [51], leads to mucin gel—Ca-HUCB interactions. Similar association of pigment gallstones has also been reported for osteopontin, a lichogenic Ca binding glycoprotein secreted by human gall-
bladder mucosa [52].

Intestinal pathobiology of bile salts and bilirubin in relation to “black” pigment gallstone formation

Important pathophysiological perturbations in the gut-liver axis controlling the homeostasis of both bilirubin and bile salts may lead to hyperbilirubinemia, the critical risk factor in formation of “black” pigment gallstones [33]. In all of these scenarios, the common denominator appears to be ileal dysfunction from any cause with spillage of malabsorbed bile salts into the cecum and large intestine.

Under physiological conditions, the bile salt pool enjoys a very efficient EHC. Bile salt molecules are retrieved from the gut via the sodium-coupled apical membrane co-transporters (SLC10A2) in the distal ileum, which is responsible for greater than 96% of bile salt conserva-
tion within the enterohepatic axis. In health, an EHC of UCB does not exist or is negligible [2]. The conjugates are too bulky and polar, intestinal deconjugation of biliru-
bin conjugates to UCB is rapid [2], and efficient reduction of bilirubin to urobilinoids prevents passive resorption of UCB [33]. Deconjugation in the gut can occur via a β-
glucuronidase of bacterial origin but also by the mammalian enzyme of sloughed enterocytes, which contain a neutral β-
glucuronidase. Luminal solubilization is crucial for induced resorption of UCB. This can occur with:

- higher rates of bilirubin deconjugation due to prolonged intestinal transit time such as during calorie deprivation with overgrowth of β-glucuronidase producing bacte-
ria, or a supply of β-glucuronidase from extraintestinal sources, such as breast milk, resulting in “breast milk jaundice” in premature infants;
- slow or absent intestinal reduction of UCB by bacteria such as present in neonates or in adults during oral antibi-
otic therapy;
- more alkaline luminal pH, higher bile salt concentrations, or agents preventing complexing of UCB with Ca2+ in the intestinal lumen.

Malabsorbed bile salts are the most obvious cause of an induced EHC of UCB. They elevate colonic detergent levels that solubilize UCB promoting its passive resorption from the intestine [53]. Even in the absence of ileal disease, ileal resorption of conjugated bile salts via SLC10A2 is dependent on intraluminal pH. A 0.5 pH unit decrease in ileal luminal pH diminishes sodium taurocholate transport by 9% per enterohepatic cycle [54]. Finally, complexing of UCB with Ca2+ in the intestinal lumen blocks its resorption and a diminution in Ca2+ concentration may lead to higher UCB lev-
els. Bile salts also bind intraluminal calcium forming soluble calcium complexes with similar results on elevating soluble UCB levels [55]. Another example of insoluble calcium salt formation depleting intraluminal Ca2+ ions occurs in the setting of dietary fat malabsorption. In this regard, intralu-
minal calcium precipitates as calcium long-chain fatty acid soaps in the proximal small intestine and becomes unavailable to bind cation-sensitive anions, such as UCB in the distal intestine, thereby increasing its solution levels. It has been proposed [53] that hyperbilirubinemia from an induced EHC of UCB represents a parallel pathophysiology to that of enteric hyperoxaluria in the setting of fat malabsorption [56].

Apart from its primary lithogenic effect, hyperbilirubin-
emia may lead to “uncoupling” of biliary lipids from bile salts at the canalicular level with diminution in their biliary secretion rates [57]. Diminished biliary secretion of biliary phosphatidylcholine and cholesterol molecules leads in turn to a lessening of their protective role on bile salt detergency. As a result, there is a higher likelihood of bile salt-induced injury to the mucosa of the bile ducts and gallbladder,
Pathogenesis of pigment gallstones

further facilitating pigment gallstone formation via production of mucosal β-glucuronidase from biliary epithelial cells, and possibly also mucin glycoproteins and reactive oxygen species (ROS) [54].

The intestinal microflora, dietary factors and pigment gallstone formation

Intestinal bacterial overgrowth occurs in several pathologic conditions and may result in increased bile salt and bilirubin deconjugation in the small intestine. This could contribute further to bile salt malabsorption and enhanced solubilization and EHC of UCB from the colon [33]. This is exemplified by intestinal hypomotility from any cause including chronic constipation [33], total parenteral nutrition [33], cystic fibrosis [33], and spinal cord injury [58]. Furthermore, bile salt malabsorption may also be caused by undigested starch and β-cyclodextrin, a starch degradation product in subjects ingesting high carbohydrate diets [59]. Likewise, high intake of refined sugars affect metabolism of intestinal microflora and prolongs intestinal transit time [60], again potentially affecting an EHC of UCB. Moreover, hypertonic solutions of sucrose increase intestinal mucosa permeability [61]. Indeed, high sucrose diets induce pigment gallstones in prairie dogs [62], a species known otherwise as a facile model of cholesterol gallstone formation [63]. Contrarywise, high dietary fibre may prevent pigment gallstone formation, because of the production of abundant short-chain fatty acids from bacterial fermentation [62]. These diminish distal intestinal pH, precipitate UCB and sequester bile acids as insoluble species in the large intestine. Such a scenario is common in subjects where an abundance of dietary fibre is a food staple, such as with vegetarians and sub-Saharan Africans known to have very low prevalences of gallstone disease [64,65]. Resorption of UCB may be impaired additionally because of bulk-induced increases in colonic transit times [66,67]. Besides direct effects of bile salts on UCB solubilization, secondary bile salt production from bacterial overgrowth may also promote release of intracellular microbial β-glucuronidase by enhancing plasma membrane permeability of bacteria [68].

Decreased concentrations of biliary β-glucuronolactone, an inhibitor of β-glucuronidase [69], was reported to be associated with black pigment gallstone disease in post-WWII Japan because of low-protein diets. A role for impaired intestinal barrier function has been proposed as a role in passive UCB resorption during experimental pigment lithogenesis in hamsters [70], as is also evidenced by high serum endotoxin levels and indices of immune cell activation in the intestinal mucosa [70,71]. In germ-free Swiss Webster, intestinal barrier dysfunction may also be a critical factor facilitating an EHC of UCB, which in the germ-free state cannot be degraded to urobinoids [72].

In black pigment gallstone formation, another potential pathogenetic factor is slow or absent bacterial reduction of intestinal UCB as evidenced by the dearth of intestinal microflora in neonates and in patients requiring prolonged oral antibiotic therapy. Absence of UCB reduction in the intestinal lumen is both a contributing factor to neonatal jaundice [73] but also for pigment gallstone disease as well as the hyperbilirubinemia associated with oral antibiotic therapy [74]. As alluded to above, Germfree Swiss Webster mice exhibit extremely high prevalences of black pigment gallstone formation spontaneously [72,75] apparently secondary to what appears to be at least four factors; inability to degrade UCB to urobinoids, decreased intestinal motility, gallbladder hypomotility from a pre-diabetic state, and diminution in intestine mucosal barrier function [72,75].

Since gallbladder inflammation is implicated in black pigment gallstone formation, it is tempting to speculate that UCB per se might be specifically involved in the immune response ultimately leading to pigment cholelithiasis. In fact, UCB has been shown to be involved in regulatory T-cell differentiation [76].

Putative role of ROS in “black” stone polymerization and oxidation

It is likely that polymerization of the HUCB− tetrapyrrole, a key event in the transition of soft yellow to hard black pigment gallstones, is initiated by free radicals or singlet oxygen species and occurs in the solid or semisolid state. A hepatic source of ROS is unlikely since Ca(HUCB)2 in “brown” stones remains unpolymerized [2]. ROS are more likely products of mucosal macrophages or neutrophils from an inflamed gallbladder that accompanies pigment stone disease [2,72,75]. This is consistent with observations of bacterially-derived oxysterols in human bile as well as in black pigment gallstones [77]. In addition, oxidative stress induces formation of bilirubin-free radicals, which are prone to polymerize easily, as evidenced by ESR and NMR studies of human pigment stones [78]. Indeed, administration of the free radical scavenger melatonin (N-acetyl-5-methoxytryptamine) is reported to prevent pigment gallstone formation in bile duct-ligated guinea pigs [79]. In addition, this appears to be the case for methionine, which acts also as a free radical scavenger. Methionine deficiency in the diet of domestic dogs is associated with increased formation of black pigment gallstones, whereas methionine supplementation counteracts lithogenesis [80]. Moreover, as inferred from ex vivo studies [81], suppression of oxidative stress in the gallbladder may well play a role in ameliorating cholesterol gallstone formation also.

Conclusions

“Black” pigment gallstones form only in the gallbladder and are due to “hyperbilirubinemia” usually from three conditions:

- hemolysis from any cause including unsuspected conditions such as malaria, hypersplenism and prosthetic neovascularule;
- ineffective erythropoiesis from vitamin B12 and folate deficiencies which are now rare in humans;
- induced EHC of UCB, a new pathophysiologic concept which has multiple predisposing factors highlighted in this review.

With respect to the latter, any or all of the factors that make more UCB soluble and available in the large intestine

facilitate its resorption to return to the liver, for reconjugation and resecretion into bile. UCB resorption may be aided by an increased permeability and residence time of UCB in the gut as well as low levels of ionized Ca$^{2+}$.

The primary source of free UCB in gallbladder bile is from endogenous biliary β-glucuronidase hydrolysis of bilirubin conjugates. This enzyme is of hepatic origin but with gallbladder inflammation can also be secreted from a biliary mucosal source. In the concentrated bile salt milieu of hepatic and gallbladder bile, UCB at biliary pH values is a monoaicid, HUCB$^-$. Two molecules of HUCB$^-$ bind with ionized biliary Ca$^{2+}$, to form a divalent salt that has miniscule solubility in aqueous systems and precipitates from solution in bile. The ROS secreted by an inflamed gallbladder mucosa apparently causes Ca(HUCB)$_2$ polymerization and oxidation [82]. The germ-free Swiss Webster mouse, a newly described animal model of "black" pigment gallstone formation [72,75], promises to answer many of the vexing questions regarding the pathophysiology and physical-chemistry of this disease.

"Brown" stones are a phase-separated artifact of bile that can form in any part of the biliary tree secondary to chronic stasis from any cause and anaerobic bacterial infection. The anaerobes secrete multiple enzymes that hydrolyse ester and amide linkages of all biliary lipids and lipopigments into calcium-sensitive anions that phase-separate as insoluble protonated anions or calcium salts. These precipitates deposit on obstructing "nuclei" such as small migratory cholesterol or "black" stones formed in the gallbladder, parasite eggs and dead worms or flukes. The Oriental hepatolithiasis syndrome is the most serious manifestation of "brown" pigment stone disease. Beginning in early life, it is initiated by nematode or fluke infestation within the extrahepatic and intrahepatic bile ducts usually favoring the left lobe of the liver; worldwide, *Ascaris lumbricoides*, *Clonorchis sinensis* and *Opisthorchis viverrini* appear to be the principal parasites involved.
